ABSTRACT

This paper describes the first part of the photometric data from the $9^\circ \times 9^\circ$ ASAS camera monitoring the whole southern hemisphere in the *V*-band. Data acquisition and reduction pipeline are described and preliminary list of variable stars presented. Over 1 300 000 stars brighter than $V = 15$ mag on 10 000 frames were analyzed and 3126 were found to be variable (1055 eclipsing, 770 regularly pulsating, 132 Mira and 1169 other, mostly SR, IR and LPV stars). Periodic light curves have been classified using the fully automated algorithm, which is described in detail. Basic photometric properties are presented in the tables and exemplary light curves are printed for reference. All photometric data are available over the INTERNET at <http://www.astrouw.edu.pl/~gp/asas/asas.html> or <http://archive.princeton.edu/~asas>.

Key words: *Catalogs – Stars: variables: general – Surveys*

1. Introduction

The All Sky Automated Survey (ASAS, Pojmański 1997, 1998, 2000) has finally achieved its important goal – photometric monitoring of the large part of the sky (Paczynski 1997). After installing two wide-field ($9^\circ \times 9^\circ$) cameras in October 2000 (Pojmański 2001) ASAS gained capability to measure brightness of the observable stars on the nightly basis.

The prototype ASAS system using small commercial CCD camera, 135 mm f/1.8 telephoto lens and *I*-band (Schott RG-9, 3mm) filter was used in the years 1997–2000 to monitor 0.7% of the sky to the limiting magnitude of $I \approx 13$ mag. During three years of operation it collected over 50×10^6 measurements of over 150 000 stars and detected almost 4000 variable stars.

The instrument, data acquisition and reduction pipeline, the ASAS Catalog and summary of the variability search were described by Pojmański (1997, 1998, 2000).

In summer 2000 we have installed upgraded ASAS-3 system in the dome of the 10" astrograph at the Las Campanas Observatory (operated by the Carnegie Institution of Washington). New hardware consisted of the three independent instruments

each equipped with the automated paralactic mount, imaging optics with standard filter, 2048×2048 ($14 \mu\text{m}$ pixels) CCD camera and dedicated computer.

Two wide-field systems are equipped with the Minolta 200/2.8 APO-G telephoto lenses giving superb sharpness ($\text{FWHM} < 2$ pixels) but also strong vignetting (40–50% in the corners). The field of view of is 8.8×8.8 . The two systems are equipped with the standard V and I filters.

Narrow field instrument, $D = 250$ mm, $F = 750$ mm, is a Cassegrain telescope with a three element, Wyne-type field corrector. It gives sharp images ($\text{FWHM} < 2.2$ pixels) in the field of 2° diameter. With 2048×2048 CCD the field of view is 2.2×2.2 . This system has I filter in its optical path.

Three AP-10 (Apogee) commercial cameras were purchased for the project. High readout noise ($> 10 e^-$) and 14 bit ADC were accepted as a trade-off for 5 sec readout time. Unfortunately two of three systems did not meet factory specifications (increased noise resulting in substantially reduced sensitivity, failed thermo-cooler) and had to be sent for repair after first months of operation. Thus ASAS-3 was left with only wide-field V -band camera working.

2. Observations

Mechanical quality of the mount allows for exposures as long as 5–10 minutes (without guiding) for wide-field systems but only 3 minute exposures are taken in the V -band giving the limiting magnitude of almost 15.0 mag and causing saturation of stars brighter than $V = 8.5$ mag.

The whole sky has been divided into 709 $8^\circ \times 8^\circ$ fields of which 422 (60%) with $\delta < +20^\circ$ can be observed from Las Campanas (up to 300 on a single summer night). Due to the obscuration by the dome only fields with $\delta < +2^\circ$ were observed by the V instrument.

The routine observing schedule for each wide-field camera consists of cycling through the list of fields and picking up the one that is the most suitable for observation at the moment. Selection algorithm was not uniform enough, so equatorial fields were observed two times less often than the circumpolar ones.

Although the sky-flats are not working properly for the wide-field instruments we use them both as the raw correction for vignetting and as the pixel-to-pixel sensitivity variation. Each night a series of sky-flat exposures is taken after the sunset, followed by dark exposures.

Between 160 and 200 frames in the V -band are taken each night (depending on the season), enabling camera to cover the whole available sky in less than two days. The raw data stream of one ASAS-3 instrument is thus about 1.5 GB per night. The loss-less compression reduces this stream to 0.7 GB per night (2–3 DAT-3 tapes per month), so we are considering some lossy compression in the future.

Fig. 1. Standard deviation σ_V of the stellar magnitudes vs. V -band magnitudes observed with wide-field V camera and 3-minute exposures for the field F0120-72-019 (containing the SMC). Larger dots denote detected variables. Small dots lying above 95 centile are mostly due to the "long-term" variables not recognized in this work.

Fig. 2. Coverage of the sky with V -band observations after one year of ASAS-3 operation. White color corresponds to the area observed at least 250 times, dark gray – at least 30. Only fields centered within $0^h < \alpha < 6^h$ are analyzed in this paper.

3. Data Reduction

The data reduction pipeline used for ASAS 1–2 observations was described by Pojmański (1998). ASAS-3 incorporates only some minor changes to that scheme.

Currently used optics gives sharp images and produces less scattered light than the previous one. In fact images can be so sharp ($\text{FWHM} \approx 1.4\text{--}1.6$ pixels) that only aperture photometry can properly deal with them. Therefore we are now mak-

ing simultaneous photometry through five apertures varying in size from 2 to 6 pixels in diameter. Data for each aperture are processed separately, so one can use data obtained with the smallest one for the faint objects and with the largest one for the brightest objects in the catalog.

Reducing ASAS-2 data we partly managed to correct photometry for saturation and bleeding and included overexposed stars in the ASAS Catalog. Unfortunately present CCD cameras do not allow for such correction so the photometry of saturated images is now practically useless.

Less scattered light in the optics (partly due to the smaller opening: $f/2.8$ vs. $f/1.8$) have substantially improved the quality of the sky-flats allowing us to obtain good first-order correction of the vignetting.

The astrometry is now based on the ACT catalog and using third order polynomials in X and Y we usually obtain positional accuracy better than 0.2 pixels (< 3 arcsec).

The zero-point offset of our photometry is based on the Hipparcos (Perryman *et al.* 1997) data. A few hundred Hipparcos stars are usually located in each $9^\circ \times 9^\circ$ field. We use them for precise offset calibration. The *rms* scatter of the difference between ASAS and Hipparcos photometry calculated for all stars lying close to the frame center is about 0.015 mag (Fig. 3a). Close to the edges it is significantly larger (Fig. 3b) due to systematic effects caused by non-perfect flat-fielding. Errors are most prominent (Fig. 3c) when we compare brightness of the stars located in the overlapping areas of the neighboring fields (Fig. 3c).

Fig. 3. Difference between Hipparcos and ASAS-3 magnitudes for all available stars.

The final catalog is divided in two parts now. The first one is relatively slow, but it is capable to store information about all sources detected on the frame. This catalog is regularly analyzed and significant measurements are piped into the second, fast-access part of the catalog. The remaining data (usually single entries caused by the image flaws) are archived separately.

All data processing is normally done in real time on the instrument's computer, but due to the necessity of fine-tuning of many elements of the pipeline we are reprocessing the data from the tapes at Warsaw headquarters.

4. Variability Search

Data analyzed in this paper cover the period of one year (2001) of unattended operation. During that time all southern sky has been observed at least 50–150 times. Over 50 000 frames have been collected in the V-band. More than 10 000 of them are in 0^h–6^h quarter of the Southern Hemisphere alone. 1.3 million of stars have been measured in this area more than 40 times. These stars were subject to variability analysis similar to that performed for the ASAS-2 data (Pojmański 2000).

First, light curves for each star in the field were extracted and median magnitude and dispersion were calculated (in each aperture separately). These were plotted on the magnitude-dispersion diagram (Fig. 1) and some centile curves were obtained. Stars lying above the 95% centile were selected for further analysis.

For each suspected star AoV period analysis (Schwarzenberg-Czerny 1989) was performed. Stars with statistics value larger than 10 were accepted. The other stars were subject to long-term variability tests: variance analysis in variable-length bins and trend analysis (average number of consecutive observations showing the same direction of brightness change). Proper thresholds for these observables were selected after tests. Finally all stars showing dispersion above 99.9% centile were added to the set.

As many as 18 000 stars have passed selection criteria and had to be inspected visually. About 3200 of them passed visual inspection. The large number of rejected stars was due to several reasons: First – small number of observations, which usually forces AoV algorithm to produce spurious (or at least hard to verify) frequencies. Second – trends (slopes) in brightness changes of some stars which were partly produced by the increasing defocusing of the optics in the course of the last two months. We decided not to include any light variation of this kind, although we are convinced that some of these are real. Third – saturation, which disappeared for some stars after they became defocused.

The relative number of variable stars detected so far (0.2% of the total) is 10 times lower than that obtained by ASAS 1–2 in the selected fields. This has been caused by several factors.

First, we have investigated only stars above 95% centile in the magnitude-dispersion diagram. In the previous data we have inspected almost 75% of the stars, discovering many low-amplitude variables. This will be done also for the present data set after the more efficient algorithm for data selection is constructed.

Second, data span is one year now vs. almost three years of previous run. Together with omitting most "trend" objects we detected now a much smaller number of long-term variables. Despite quite subjective discrimination between "periodic" and "long-term" variables we classified previously about 400 stars (0.26% of the observed sample) as periodic objects and 3400 (2.2%) as long-term variables vs. 2200 (0.16%) and 1000 (0.08%), respectively, now.

Third, number of data points for each star is on average a few times smaller than in ASAS-2 data.

Fourth, data sampling was different – a few times per night previously vs. once per night now. This resulted in tremendous aliasing problems. In many cases it was not possible to decide which of many possible frequencies ranging from 0.1 day to 10 days is correct. In the case of serious doubts we usually listed the frequency corresponding to the highest peak in the power spectrum. We will solve this problem in the future observing each field for some time in the "high frequency" mode – at least several times per night. As for now we can only present our best choice and try to improve lists available on the INTERNET as soon as new data are available.

506 variable stars observed by ASAS-2 are located in the currently analyzed region. 466 of them were observed with the ASAS-3. Most of the remaining objects were faint in the *I*-band, so probably were too faint for *V* observations. One star was bright (053820–6937.4 $I \approx 9.69$ mag), but since it is an irregular variable it might have faded below our *V* detection limit. Only about 100 of 466 stars were detected to be variable in the *V*-band by the present analysis.

62 other objects were selected by the detection algorithm but were rejected after visual inspection. Only 3 of them were of "periodic" type and in all cases primary rejection reason was a small number of points and low power in spectrum. In one case (053936–7958.6) light curve had an amplitude of 0.1 and only 40 data points. ASAS-2 has easily detected its variability with almost 4000 measurements. The rest of the light curves that did not pass visual inspection were of the "long-term" type and were rejected either because of the "trends" described above or small number of points.

The other 300 (65%) stars were not even preselected by the selection algorithm, again due to either small number of data or too small changes in brightness. In most cases, however, plotting their light-curves folded with the known period clearly reveals periodic variation.

5. Variability Classification

Only 2000 of the 18 000 stars in the initial set of the candidate variable stars were selected by a quite robust long-term selection algorithm. Almost 1500 of them have passed visual inspection.

The other 16 000 stars were selected by the AoV algorithm, thus their folded light curves had to be inspected visually one by one. Unfortunately, the relative number of true variables dramatically decreases as the AoV statistics comes closer to the detection threshold (which was set to 10), making verification process highly non-efficient.

Survey catalogs do not necessary need to provide object classification, but their usefulness increases if they do. However, since the volume of data is growing rapidly, such step requires some automation providing necessary speed, repeatability and consistency.

Several attempts have been made so far to create classification machines usually based on neural networks and machine learning (*e.g.*, Eyer and Blake 2002, Woźniak *et al.* 2002b) or on direct parametric analysis (*e.g.*, Udalski *et al.* 1999, for Cepheids, Szymański, Kubiak and Udalski 2001 for contact binaries).

Here we propose simplified approach that mimics nonlinear neural network behavior which parameters ("weights") can be easily defined in terms of the light curve parameters. "Teaching" in this case is done by defining the multidimensional solids describing selected classes. Classification could then be done by selecting the closest solid in the multidimensional parametric space. To simplify our task we use carefully selected two-dimensional cross-section of that space.

Ruciński (1993) showed that light curves of the contact configurations of W UMa systems can be easily described using only two coefficients, a_2 and a_4 , of the cosine series $\sum a_i \cos(2\pi i\phi)$. Following his work we tested behavior of semi-detached and detached configurations in the a_2 – a_4 plane.

The large set (4500) of theoretical light curves was calculated using the Wilson-Devinney code (1972) for a wide range of binary parameters: masses M_1 , M_2 temperatures T_1 , T_2 and radii R_1 , R_2 characteristic for the main sequence O–M stars, periods P varying from the contact configuration to 100 days and inclinations i in the range of 60–90 degree. For each combination of M_1 , M_2 , P we varied R_1 and R_2 between the main sequence size and Roche lobe.

Harmonic series of the form:

$$\sum_{i=1}^4 a_i \cos(2\pi i\phi) + b_i \sin(2\pi i\phi) \quad (1)$$

was then fitted to all light curves.

Fig. 4a shows the relation between coefficients a_2 and a_4 . Filled and open dots represent contact and detached configurations, respectively, while pluses and crosses denote semi-detached configurations with primary and secondary component filling Roche lobe, respectively. Grey area covers over-contact configurations calculated by Ruciński (1993, Fig. 6).

Fig. 4a clearly indicates that in most cases contact, semi-detached and detached configurations can be unambiguously distinguished in the a_2 – a_4 plane. However, looking at individual light curves one can note some confusion introduced by widely used EW, EB, EA classification of the light curves: contact or almost contact configurations do not necessarily have minima of the same depth; there are frequent semi-detached configurations with equal minima; detached binaries do not necessarily have flat maxima. Thus, although often used in such context, EW, EB and EA classes do not correspond entirely to the contact/detached discrimination. Since we feel that the latter is physically more interesting, we would prefer to recognize "c", "sd", and "d" configurations. Thus, we will classify as EC the contact configurations lying above the upper line in Fig. 4a, as ED – the detached binaries located below the lower line, and as ESD – the remaining semi-detached systems located between dashed lines.

Fig. 4. Distribution of light curves in the a_2 – a_4 plane. a) Data obtained from the Wilson-Devinney simulation are plotted. Grey area encloses over-contact models calculated by Ruciński (1993). Two continuous lines delineate contact and detached configurations, while semi-detached systems are located between dashed lines; b) Eclipsing variables from OGLE Bulge database (Woźniak *et al.* 2002a); c) ASAS eclipsing binaries (this paper); d) OGLE Bulge pulsating variables.

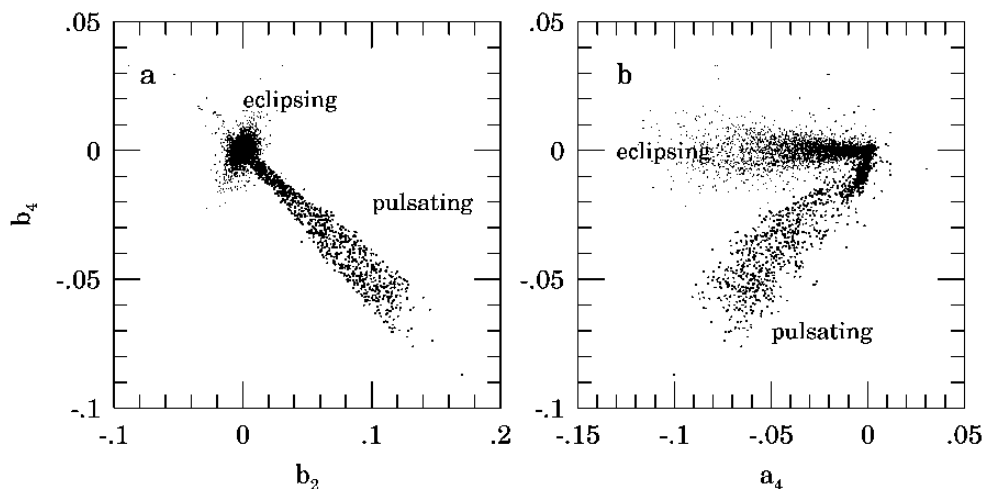

Fig. 5. Separation of eclipsing and pulsating variables in a) b_2 – b_4 and b) a_4 – b_4 planes. Data plotted are for the OGLE Bulge variables.

In the case of real data some additional steps have to be taken before applying Fourier decomposition. First, the “base” frequency, f_0 , that equals to the frequency of the eclipsing system and is half the pulsation frequency for the pulsating stars has to be located in the power spectrum. AoV spectrum puts most of the power either into $2f_0$, f_0 or even $2/3f_0$, depending on the light curve shape and distribution of observations – complicating automation of the process.

Fortunately a slightly slower ORTPER code (AoV Multiharmonic Periodogram for Uneven Sampling, Schwarzenberg-Czerny, 1996) usually properly selects $2f_0$ for the pulsating stars and f_0 or $2f_0$ for eclipsing light curves. The final test on f_0 is done performing Fourier decomposition using f_0 . In properly phased light curve we expect the a_2 term to be dominant, so if we obtain $a_4/a_2 > 1$ we have to halve the initial value of f_0 .

The second step necessary for direct comparison of the Fourier coefficients is a consistent zero phase determination. We do that by locating minimum on the reconstructed light curve. In the present work we only use the first four harmonics. This reduces our ability to recognize tiny features on the light curves in return for smaller coefficient scatter.

Large data set of uniform light curves is necessary to efficiently divide parametric volume into solids corresponding to different classes. We have used three major sources of data: our own (ASAS) light curves that were provisionally classified into DSCT, RRAB, RRC, DCEP, EW, EB and EA classes; OGLE SMC and LMC Cepheids (Udalski *et al.* 1999a, 1999b) carefully divided into DCEP_{FU} and DCEP_{FO} (fundamental and first overtone) classes; and subset of OGLE Bulge variables (Woźniak *et al.* 2002a), that were provisionally divided into pulsating and eclipsing groups.

In Fig. 4b the OGLE Bulge eclipsing variables are plotted, while in Fig. 4c ASAS data from this paper. It is interesting that in the case of OGLE data significant deficiency of the semi-detached systems could be spotted.

In Fig. 4d the OGLE Bulge pulsating stars are plotted to show that a_2 – a_4 plane cannot be used for separating pulsating and eclipsing systems. Instead b_2 – b_4 or a_4 – b_4 coefficient pairs (Fig. 5ab) provide necessary segregation.

Finally we need to recognize different types of pulsating stars. We have done this using $a_{42} = \frac{a_4}{a_2}$ vs. $\varphi_{42} = \varphi_4 - \varphi_2$ (radial coordinates, Fig. 6ab) and $\log P$ vs. a_{42} (Fig. 6cd) diagrams, on which categorized ASAS data and OGLE Bulge pulsating stars were plotted. The latter one is an equivalent of the well known R_{21} vs. $\log P$ diagram used for Cepheid classification. Although ASAS data were scattered, they provided necessary clues to locate different classes of variables in the above diagrams. However, final sharp polygons in both planes were determined using better quality data from the OGLE Bulge catalog.

Besides the period P three other non-Fourier parameters describing light curves were needed to reduce the number of wrong classifications: two describing difference in minima and maxima levels and the third describing vertical asymmetry of

Fig. 6. Distribution of light curve parameters in the $a_{42}-\phi_{42}$ and $\log P-a_{42}$ planes for OGLE (a,c) and ASAS (b,d) variables. Tiny dots in the upper panel are eclipsing binaries, while all larger ones – pulsating.

the light curve (fraction of measurements above the average level). They were necessary, because the fourth order harmonics could not properly recognize narrow, unequal minima or sharp maxima.

Process of automated classification is now straightforward: Each class is described by a set of polygons in several cross-sections of the parametric space. In each plane score function is calculated: it equals 1.0 inside the polygon and decreases exponentially outside the polygon. The rate of decrease depends on the accuracy of the parameter, so we allow large deviations for noisy data. All scores are multiplied and the class with the highest result is selected as a winner. If, however, other classes have similar scores (at least 75% of the maximum) multiple classification is accepted. If the highest score is below 0.50 uncertainty flag (:) is added, while for very low scores (less than 0.2) general class of PULS was applied. So far we have defined three eclipsing classes: EC, ESD, ED and six pulsating: DSCT, RRAB, RRC, DCEP_{FU}, DCEP_{FO}, M.

Such algorithm has many advantages. It is fast, easy to verify and very flexible. Adding new parameters (like location in color-magnitude or period-luminosity diagrams, spectral type etc.) is simple and needs only defining a new polygon in the parametric space. The obvious disadvantage is that only predefined classes could be selected.

In this paper, using only one filter photometric data, we are in fact classifying data according to the light curve shape and period only. Therefore caution must be taken not to over-interpret results: Many RRC objects might be in fact EC or DSCT. The algorithm will usually recognize and mark such situations. DCEP classes are based on the SMC/LMC data and will not entirely correspond to the Galactic objects. DCEP_{FU} are usually easily recognized by their RRAB-like shapes, but around $\log P = 1$ many sinusoidal cases are encountered and probability of wrong identification increases. M (Mira) class was defined for objects with $\Delta V > 2$ mag and $P > 70^d$, so some SR, IR and even CV objects might have been also classified as M.

We have discovered many “M” shaped variables, both in ASAS and OGLE data, with periods of tens of days. The algorithm tends to classify them as EC or ESD, implying they are contact or semi-detached giant stars. In fact, in case of OGLE variables most of them are located close to the Red Clump (Udalski, private communication), so there is no inconsistency. This is why we did not restrict EC class to the short periods only.

Another problem with automated classification is caused by semiregular and irregular variables, which often show strong signal in the power spectrum. Unless detected by other means these stars have a good chance to be falsely classified. We have tried to define SR and IR classes in terms of long-term variations in the light curve, but results are not satisfactory yet. For the present analysis we decided to relay on the initial visual inspection of light curves, during which we have selected about 1100 irregular ones that were marked as MISC and were not subject to automated classification. These are mostly semiregular (SR), irregular (IR), slow irregular (L), LBV and other less regularly changing stars with time scales of variation between 10 and 200 days.

6. The Catalog

Current list of candidate variable stars in the first quarter of the Southern Hemisphere contains 3126 stars.

For each star the following data are provided: ASAS identification ID (coded from the star's α_{2000} and δ_{2000} in the form: hhmmss-ddmm.m), period P in days (or characteristic time scale of variation for irregular objects), T_0 – epoch of minimum (for eclipsing) or maximum (for pulsating) brightness, V_{\max} – brightness at maximum, ΔV – amplitude of variation, Type – one of the predefined classes: EC, ESD, ED, DSCT, RRC, RRAB, DCEP_{FU}, DCEP_{FO}, M, PULS and MISC.

67 stars marked with “:” were inspected visually, and in about 20 cases original classification was changed (in most cases for highly distorted ED curves, that were classified as pulsating ones). 680 objects have multiple classification. For 330 cases this is exclusively due to EC/ESD or ED/ESD confusion, but for 180 other this is a more serious EC/RRC or EC/DSCT double classification. Quite often visual inspection may help to remove such degeneracy.

ELL and SR suffixes were added in several (54 and 45) cases for almost purely sinusoidal light curves and for evident long term light curve variations, respectively.

Search for detected variables in the SIMBAD database revealed only 800 matches with stars known to be variable (almost 200 of them are in the the SMC and LMC fields), so over 75% of stars are probably new detections.

Table 2

Number of various types of variable stars detected on
5000 square degrees by ASAS-3 V camera

Type	Count	Type	Count
DCEP _{FU}	189	EC	654
DCEP _{FO}	67	ESD	248
DSCT	143	ED	150
RRAB	245	M	132
RRC	111	MISC	1176
PULS	11		

Table 1 contains a compact version of the catalog. Only three columns are listed for each star: identification ID, V , and ΔV . Column ID also contains some flags – ":" if classification was uncertain, "?" if multiple classes were assigned (objects were grouped in the table according to the highest rank assignment), "v" if SIMBAD lists a star to be variable. Table 2 summarizes our classification effort.

Appendix shows exemplary light curves. Only ID is given for each. For periodic variables phase in the range $(-0.1, 2.1)$ is plotted along the x -axis, while for Mira's and miscellaneous stars – HJD in the range $(2451800-2452300)$. On the y -axis magnitudes are given. Larger ticks always mark 1 magnitude intervals and vertical span is never smaller than 1 mag.

The full catalog of variables observed by the ASAS system, containing more classification details, as well as complete data for the light curves, is available over the INTERNET:

<http://www.astrouw.edu.pl/~gp/asas/asas.html>

or

<http://archive.princeton.edu/~asas>

7. Conclusions

We have presented preliminary results of the search for variable stars in the Southern Hemisphere. Only a quarter of available data covering right ascension between 0^h-6^h has been presented in this paper, due to the tremendous effort necessary for visual verification of light curves. Over 3000 variable stars were found so far among 1 300 000 stars brighter than $V \approx 15$ mag. Comparison to the ASAS-2 data suggests, that the number of variable stars should increase 3–10 times, as more observations are collected.

Most of these stars belong to the "periodic" class, as we have not included many candidate objects for the "long-term" variation. There is a large subset of bright ($V < 12$ mag) detached binaries – useful for distance scale calibration – perfect targets for small size spectroscopic instruments.

Fully automated classification algorithm, described in this paper, efficiently separates stars into predefined classes. For a good quality data its efficiency reaches 100% in those regions of the parametric space, where the classes do not overlap. In doubtful cases alternative classes are always proposed. Currently our algorithm works properly only if the highest peak in the power spectrum corresponds to the true frequency or one of its harmonics, which is not necessarily true for noisy, poorly sampled data. What is still missing is a robust algorithm that will allow to separate light curves into strictly periodic and irregular ones.

However, at this time we feel it is better to publish imperfect data, to allow larger number of astronomers to see the diversity of raw results and to work on variety of scientific topics. Note a recent paper by Pietrukowicz (2001), who used the past ASAS data to determine period changes in the LMC Cepheids.

Processing of the remaining ASAS data is in progress, so we plan to release next parts of this catalog in the near future. In addition, at present four ASAS instruments, covering the whole southern sky each night, are taking data. Over 120 000 images have been collected so far in the V , I and R bands, covering the whole hemisphere more than 300 times. Soon real time photometry will be achieved, finally allowing us to setup the Early Warning System.

Acknowledgements. This project was made possible by a generous gift from Mr. William Golden to Dr. Bohdan Paczyński, and funds from Princeton University. It is a great pleasure to thank Dr. B. Paczyński for his initiative, interest, valuable discussions and the funding of this project.

I am indebted to the OGLE collaboration for the use of facilities of the Warsaw telescope at LCO, for their permanent support and maintenance of the ASAS instrumentation, and to the Observatories of the Carnegie Institution of Washington for providing the excellent site for the observations. I am especially indebted to Dr. M. Kubiak for providing selected light curves from the OGLE Bulge database.

This research has made use of the SIMBAD database, operated at CDS, Strasbourg, France. This work was partly supported by the KBN 2P03D01416 grant.
